State Estimation Utilizing Multiple Description Coding over Lossy Networks

Zhipu Jin, Vijay Gupta, Babak Hassibi, Richard M. Murray

Abstract—For state estimation in networked control systems, the impact of packet dropping and delay over network links is an important problem. In this paper, we introduce multiple description (MD) source coding scheme to improve the statistical stability and performance of the estimation error covariance of Kalman filtering with packet loss. We consider about two cases: when the packet loss over network links occurs in an i.i.d. fashion or in a bursty fashion. Compared with the traditional single description source coding, MD coding scheme can greatly improve the performance of Kalman filtering over a large set of packet loss scenarios in both cases.

I. INTRODUCTION

A standard assumption in classical control theory is that the data can be transmitted to the controller or state estimator reliably and with infinite precision, or at most corrupted by an additive Gaussian white noise. Thus we need reliable communication channels with infinite bandwidth. However, in the real world, any communication link has a limited channel capacity and data packets may be dropped. There is increasing attention being given to consider the effects of finite bit rate and stochastic packet losses, especially in the field of networked control systems (NCS) where the standard assumption is challenged most severely. Works like [1], [18], [19], [23], [25] have focused on answering the question: how much capacity do we need to achieve a certain control performance or estimation accuracy? In this paper, we are interested in another issue: how does the unreliability of the communication network affect NCS and what can we do to compensate for this unreliability? More specifically, we want to find out how we can improve the state estimation with the presence of stochastic packet loss.

Most of the modern digital communication systems are implemented using packet-based communication protocols. Typically packet-based systems use a progressive source encoder to generate packets and deliver them with standard protocol like the transmission control protocol (TCP). For real-time networked control systems, this scheme faces couple of serious problems:

• TCP automatically retransmits lost packets which generates large delays.
• For progressive coding, the arriving order of the packets is critical. This coding scheme works well only when the packets are sent and received in order without loss.

There may not be reliable or cheap reverse channels from decoders to encoders to introduce feedbacks and cannot guarantee efficient retransmission.

We make the following general assumptions:

• Each data packet is time-stamped and protected from channel noise by perfect channel coding. The packet will be either received and decoded successfully at the end of the links or totally lost.
• There are not computation delays, such as coding delay, shaping delay, packetisation delay, or receiver play out delay. Also we omit WAN propagation and queueing delay. The only delay may be considered here is the transmission delay.
• We model the packet losses either according to an i.i.d. process (the Bernoulli model in [26]) or according to a Markov chain (the Gilbert-Elliott channel model in [2], [6]). The Markov chain model can handle bursty channel losses.
• The network does not provide preferential treatment to some packets. In other words, the network treats each single packet equally without inspecting the content. Thus a multiple resolution code or a layered source code is not a good choice for us.
• There is no feedback from decoders to encoders over the networks.

In this paper, we focus on state estimation of a dynamical system over a packet dropping link. We choose the error covariance matrix of the estimation as our metric of the performance of the estimator. In their outstanding work, Sinopoli et al. [17] used a Modified Algebraic Riccati Equation (MARE) to solve the Kalman filtering problem with intermittent observations and discussed the statistical convergence properties of the estimation error covariance. Liu et al. [14] extended the approach to solve the case with partial observation losses in sensor network. These works showed that the packet loss degrades the performance of Kalman filtering. In this paper, we are interested in

improving the performance of the estimator by using network source coding [4]. The specific scheme we consider is the multiple description (MD) source coding. MD coding has been studied in information theory for over 30 years [5], [7] and has been successfully used in transmission real-time speech, audio/video over internet [9], [11], [13]. It has been showed that MD has very good performance in the cases where the data can be used at various quality levels. However, this is the first time such schemes have been applied to NCS.

This paper is organized as follows. In Section II, we introduce the MD source coding and briefly describe the theoretical limits. Then, in Section III, the quantization noise of MD is modelled by gaussian white noise asymptotically. We formulate the problem in Section IV and present results for i.i.d. Bernoulli loss model. Some examples and simulation results are listed in Section V. We then study MD over Markov chain model in Section VI and summarize the conclusions in Section VII.

II. MULTIPLE DESCRIPTION SOURCE CODING

Multiple description source coding [4] is used to generate a network source code that can achieve good rate-distortion performance over lossy links. The unique feature of MD is that instead of using one single description to represent one possible output of the source, MD coding uses two or more descriptions. The distortion of the decoder output depends on how many descriptions it receives and can be in various quality levels. The order of descriptions is not important since MD coding is not hierarchical. The design of MD coding is a problem of optimizing the code over the redundancy and independence between descriptions. Since losses in transmission are inevitable, MD coding must make all the received descriptions as useful as possible and has to sacrifice some compression efficiency.

![Diagram of MD source coding with two channels and three receivers](image)

Fig. 2. Scenario for MD source coding with two channels and three receivers

In its original form, MD coding refers to the case depicted in Fig. 2 and we call it 2-description MD problem. A sequence of source values \( \{X_k\}_{k=1}^N \) is sent to three receivers over two noiseless channels. The encoder generates 2 descriptions for each source value and sends them through two different channels. One decoder receives the descriptions from both channels and we call it the central decoder. The reconstruction sequence at the central decoder is \( \{\hat{X}_k^0\}_{k=1}^N \). The other two decoders receive the information only over their respective channels and we call them the side decoders. The reconstruction sequences are \( \{\hat{X}_k^1\}_{k=1}^N, i = 1, 2 \). The transmission rate over channel \( i \) is denoted by \( R_i, i = 1, 2 \).

The three distortions are defined as:

\[
D_i = \frac{1}{N} \sum_{k=1}^N E\left[ \delta_i\left(X_k, \hat{X}_k^i\right) \right],
\]

for \( i = 0, 1, 2 \), where the \( \delta_i(\cdot, \cdot) \)s are distortion measures. For now on, we let

\[
\delta_i\left(X_k, \hat{X}_k^i\right) = \delta\left(X_k, \hat{X}_k^i\right) = \|X_k - \hat{X}_k^i\|_2.
\]

If \( R_1 = R_2 \) and \( D_1 \approx D_2 \), then we call the MD code is balanced. The MD problem can be generalized to \( L(>2) \) channels and we call it \( L \)-description MD coding [22].

The main theoretical problem in MD coding is to determine the achievable quintuple \( (R_1, R_2, D_0, D_1, D_2) \). As pointed out in [5], the fundamental tradeoff in MD is making descriptions individually good and sufficiently different at the same time.

For the packet-based network, we use balanced MD coding and assume \( R_1 = R_2 = R \gg 1 \) and \( D_1 = D_2 \ll 1 \). Then we have the inequality [20]

\[
D_0 \cdot D_1 \geq \frac{1}{4} 2^{-4R}.
\]

This means the product of central and side distortions is approximately lower-bounded by \( 4^{-1}2^{-4R} \). If \( D_1 \approx D_2 \approx 2^{-2(1-\alpha)R} \) with \( 0 < \alpha \leq 1 \), then the best distortion of the central distortion is

\[
D_0 \approx \frac{1}{4} 2^{-2(1+\alpha)R}.
\]

This shows the tradeoff between central and side distortions. The penalty in the exponential rate of decay of \( D_1 \) (the difference from the optimal decay rate) is exactly the increase in the rate of decay of \( D_0 \).

These bounds can be approached when a long sequence of source symbols is coded. Since in NCS, the source data are the real values of the observations, so the MD scalar quantizer (MDSQ) is a natural choice. The balanced 2-description MDSQ can be developed by the algorithm proposed in [21], and can be easily extended to 3-description or 4-description case. The first part of Table I shows some examples of the Mean Square Errors (MSE) for different description loss cases when we keep the central distortion constant. In order to get same accuracy, we need more bits per source sample (bps). The second part shows that MSE becomes bigger when the number of descriptions per sample increases when we keep bps constant. On the table, “lost \( k \)” means \( k \) of the descriptions has been lost, and “N/A” means not available.

For some other MD codes whose central decoder have same distortions, the MSEs are also listed in second part of Table I. It shows that we have to use more bits for MD if we want to get same central MSE. The MD coding actually provides various quality levels corresponding to how many descriptions the decoder receives.

The similarity between the original 2-channel MD case (shown in Fig.2) and the 2-description MD with packet-based networks in NCS is obvious. We put 2 descriptions of

Each source sample value is divided into 2 different packets and sent out in one sampling cycle. Each packet goes through the network independently. At the end of the link, the distortion of the MD decoder only depends on how many descriptions successfully pass the networks. Overtime delay equals to packet dropping since old data will not be used for real-time state estimation or control laws.

The MD coding increases the computational complexity since the size of look-up tables increases a lot at the decoder side. For example, for the traditional uniform quantizer with N levels, the look-up tables for L-description coding will be \((2^L - 1) \cdot N\). Obviously, we need to consider this issue when choosing the number of the descriptions. In most cases, 2-description MD code should be good enough.

### III. Modelling Quantization Noise

As discussed in [15], the quantization error of a uniform scalar quantizer with the assumptions of small cells, reproduction levels at the cell’s midpoints, and large support region can be approximated modeled as additional orthogonal white noise to the quantizer input.

\[
\begin{array}{ccccccc}
\text{X} & \text{Uniform Scalar} & \text{Y} \\
\text{X} & \oplus & \text{N} & \text{Y} \\
\end{array}
\]

Fig. 3. Additive noise model of uniform scalar quantization

According to Section II, the central decoder actually is a uniform scalar quantizer with the midpoints as the outputs and the mean square error (MSE) is \(D_0 \approx \Delta^2\) where \(\Delta\) denotes the width of a quantization cell.

As discussed in [20], the side decoders introduce a slight asymmetry between the two side distortions and cause a small increase in distortion. However, as the bit rate increases, this asymmetry asymptotically disappears as does the increase in distortion. According to the relationship we discussed in Section II, we have

\[
D_1 \approx D_2 \approx C_1 \cdot \left(\frac{C_2}{12}\right)^{1+\gamma} \cdot \left(\Delta \frac{1-\gamma}{1+\gamma}\right)^2.
\]

For the balanced 2-description MD coding, when \(\alpha\) is a constant, \(D_1\) will be asymptotically negligible relative to \(\left(\Delta \frac{1+\gamma}{\gamma}\right)^2\). So as long as the rate \(R_1 = R_2\) is big enough, the addition noise model is good enough to represent the quantization noise for the side decoders. In this paper, we model the MD quantization noise as Gaussian white noise with zero mean and covariance matrices is \(D_0\) for central decoder and \(D_1\) for side decoder.

### IV. Statistical Convergence of Kalman Filter using MD

#### A. Problem Formulation

Consider the following discrete time linear dynamic system:

\[
\begin{align*}
\dot{x}_t &= Ax_t + w_t \\
y_t &= Cx_t + v_t
\end{align*}
\]

where \(x_t \in \mathbb{R}^n\) is the state vector, \(y_t \in \mathbb{R}^m\) is the output vector, \(w_t\) and \(v_t\) are Gaussian white noise vectors with zero mean and covariance matrices are \(Q \geq 0\) and \(R > 0\) respectively. It is well known that if the pair \((A, Q^\frac{1}{2})\) is controllable, the pair \((A, C)\) is detectable, and no measurement is lost, the estimation error covariance of Kalman filter converges to a unique value from any initial conditions. The encoded measurement is transmitted through the network. The packets are lost stochastically. In this Section, we concentrate on the case that packet dropping are independent, identically distributed. Section VI deals with the bursty loss case.

In this work, we use 2-description balanced MD coding scheme. The measurement output \(y_t\) goes through a MD encoder and is changed into two descriptions \(i_t, j_t\). These two descriptions are put into two packets and transmitted separately. We use the variables \(\gamma_{i,t}\) and \(\gamma_{j,t}\) to indicate whether the description \(i_t\) and \(j_t\) are received correctly. If \(i_t\) is received correctly, then \(\gamma_{i,t} = 1\), otherwise, \(\gamma_{i,t} = 0\), and similarly for \(\gamma_{j,t}\). As stated above, we assume that \(\gamma_{i,t}\) and \(\gamma_{j,t}\) are i.i.d. Bernoulli random variables with the probability distribution \(P(\gamma_{i,t} = 1) = P(\gamma_{j,t} = 1) = \lambda\).

Since \(i_t\) and \(j_t\) are independently lost or received, we can have three measurement rebuild scenarios. First, we may receive both of the descriptions correctly and the measurement noise will be the white noise \(v_t\) plus the central distortion. We
use $R_0 = R + D_0$ to indicate its covariance. Second, we may receive only one description correctly and the measurement noise will be $R_1 = R + D_1$ where $D_1$ is the side distortion. Third, we may receive none of the descriptions correctly, then the measurement corrupted with an infinitely large noise. So the measurement noise is changed into a random variable $\hat{v}_t$ after the decoder at the end of the link and for the covariance $Cov_t$ we have:

$$Cov_t = \begin{cases} R_0 : & \text{probability is } \lambda^2 \\ R_1 : & \text{probability is } 2(1-\lambda)\lambda \\ \sigma^2 I : & \text{probability is } (1-\lambda)^2 \end{cases}$$

where $\sigma \to \infty$.

The Kalman filter recursion thus becomes stochastic and the error covariance evolves as

$$P_{t+1} = AP_tA^t + Q - \gamma(t,r)\frac{1}{\gamma(t,r)}AP_tC_t[CPC_t + R_0]^{-1}CP_tA^t$$

$$= (1-\gamma(t,r))\frac{1}{\gamma(t,r)}AP_tC_t[CPC_t + R_1]^{-1}CP_tA^t.$$

This is a stochastic recursion and the sequence of the error covariance matrix $P_{t=0}$ is a random process for a given initial value. Using the same approach discussed in [17], we define the Modified Algebraic Riccati Equation (MARE) for the Kalman filter with MD coding scheme as follows:

$$g_\lambda(X) = AXA^t + Q - \lambda^2AXC_tCXC_t + R_0)^{-1}CXA^t$$

$$-2(1-\lambda)\lambda AXC_tCXC_t + R_1)^{-1}CXA^t$$

where $\lambda$ is the probability that a single packet can be received correctly.

**B. Convergence Conditions and Boundaries**

This subsection lists all the theorems which are used to study the convergence properties of the MARE. For brevity, we omit the proofs which follow the ones given in [17], [?] and can be found in [12]. Considering the new MARE, we have the following theorem which states the uniqueness of the solution.

**Theorem 4.1:** Let the operator

$$\phi(K_0, K_1, X) = (1-\lambda)^2 (AXA^t + Q)$$

$$+ \lambda^2 F_0XF_0^t + V_0$$

$$+ 2(1-\lambda)\lambda (F_1XF_1^t + V_1)$$

where $F_0 = A + K_0C$, $F_1 = A + K_1C$, $V_0 = Q + K_0R_0K_0^t$, and $V_1 = Q + K_1R_1K_1^t$. Suppose there exists $K_0$, $K_1$, and $P > 0$ such that $P > \phi(K_0, K_1, P)$, then we have

(a) for any initial condition $P_0 > 0$, the MARE converges, i.e. the iteration $P_{t+1} = g_\lambda(P_t)$ converges, and the limit is independent of the initial value:

$$\lim_{t \to \infty} P_t = \lim_{t \to \infty} g_\lambda(P_0) = \bar{P};$$

(b) $\bar{P}$ is the unique positive semi-definite solution of MARE function $\bar{P} = g_\lambda(P)$.

The following theorem relates the packet receiving probability and the convergence of the MARE.

**Theorem 4.2:** If $(A, Q^\frac{1}{2})$ is controllable, $(A, C)$ is detectable, and $A$ is unstable, then there exists a $\lambda_c \in [0, 1)$ such that

(a) $\lim_{t \to \infty} E[P_t] = +\infty$ for $0 \leq \lambda \leq \lambda_c$ and some initial condition $P_0 > 0$,

(b) $E[P_t] \leq M_{P_0} \forall t$ for $\lambda_c < \lambda \leq 1$ and any initial condition $P_0 > 0$,

where $M_{P_0} > 0$ depends on the initial condition $P_0$.

This theorem states that there exists a critical value of the packet receiving probability. If $\lambda$ is smaller than that value, the MARE doesn’t converge and the error covariance matrix will diverge.

**Theorem 4.3:** Let

$$\lambda = \arg \inf_\lambda \|S \| \hat{S} = (1-\lambda)^2 A\hat{S}A^t + Q = 1 - \frac{1}{\alpha}$$

$$= \arg \inf_\lambda \|X \| X > g_\lambda(X)$$

where $\alpha = \max |\sigma_i|$ and $\sigma_i$ are the eigenvalues of $A$. Then

$$\lambda \leq \lambda_c \leq \bar{\lambda}.$$

This theorem states the upper and lower bound of the critical value of the packet receiving probability. The lower bound is in closed form and the next theorem states how to get the upper bound. For some special cases, these two bounds are identical and we will discuss them later. According to [17], for the traditional single description coding, the lower bound is $1 - \frac{1}{\alpha}$. So MD coding pushes the lower bound to a smaller value and guarantee the convergence over a larger area.

**Theorem 4.4:** Assume $(A, Q^\frac{1}{2})$ is controllable and $(A, C)$ is detectable, then the following statements are equivalent:

(a) $\exists \hat{X}$ such that $\hat{X} > g_\lambda(\hat{X});$

(b) $\exists (K_0, K_1, \bar{X}) > 0$ such that $\bar{X} > \phi(K_0, K_1, \bar{X});$

(c) $\exists \bar{Z}_0, \bar{Z}_1$ and $0 < Y \leq I$ such that $\Psi(Y, \bar{Z}_0, \bar{Z}_1) > 0$

$$\Psi(Y, \bar{Z}_0, \bar{Z}_1) = \begin{bmatrix} Y & \Delta(Y, \bar{Z}_1)' & \Omega(Y, \bar{Z}_0) & \Pi(Y) \\ \Delta(Y, \bar{Z}_1) & Y & 0 & 0 \\ \Omega(Y, \bar{Z}_0)' & 0 & Y & 0 \\ \Pi(Y)' & 0 & 0 & Y \end{bmatrix},$$

$$\Delta(Y, \bar{Z}_1) = \sqrt{2(1-\lambda)}\lambda(YA + Z_1C), \Omega(Y, \bar{Z}_0) = \lambda(YA + Z_0C),$$

and $\Pi(Y) = (1-\lambda)YA.$

According to this theorem, we can get the following corollary to reformulated the computation of $\bar{X}$ as the iteration of an LMI feasible problem.

**Corollary 4.5:** The upper bound $\bar{X}$ is given by the solution of the following optimization problem,

$$\bar{X} = \arg \min_\lambda \left( \Psi(Y, \bar{Z}_0, \bar{Z}_1) > 0 \right)$$

where $0 < \bar{Y} \leq I$.

**Theorem 4.6:** Assume $(A, Q^\frac{1}{2})$ is controllable, $(A, C)$ is detectable, and $\bar{X} < \lambda$, then for any initial condition $E[P_0] \geq 0$,

$$0 \leq \bar{S} \leq \lim_{t \to \infty} E[P_t] \leq \bar{V}$$
where $\overline{S}$ and $\overline{V}$ are solutions of the equations $\overline{S} = (1 - \lambda)^2 A \overline{S} A' + Q$ and $\overline{V} = g_\lambda(\overline{V})$ respectively.

This theorem shows the upper and lower bound of the error covariance matrix when MARE converges. The lower bound $\overline{S}$ can be computed by standard Lyapunov Equation Solvers and the upper bound $\overline{V}$ can be either computed via iterating $V_{t+1} = g_\lambda(V_t)$ from any initial condition or transferred to a semi-definite programming (SDP) problem.

C. Special Cases

There are some special cases in which the upper and lower bound of the critical value $\lambda_c$ are identical.

(a) $C$ is invertible. In this case, we choose $K_0 = K_1 = -AC^{-1}$ to make $F_0 = F_1 = 0$. Then the LMI in theorem 4.4 is equivalent to

$$X - (1 - \lambda)^2 AXA' > 0.$$  

Since $X \geq 0$ exists if and only if $(1 - \lambda)A$ is stable, i.e. the eigenvalues of $(1 - \lambda)A$ is smaller than 1, we get $\lambda = \lambda_c = 1 - \gamma$.

(b) The matrix $A$ has a single unstable eigenvalue. As long as $(A, C)$ is detectable, we can always use decomposition to transform the system so that the Kalman filter only needs to estimate a single state system. Then it follows that the lower bound and upper bound are identical.

V. EXAMPLES AND SIMULATIONS

In this section some examples and simulation results are given to show how the MD coding affects the performance of the Kalman filtering. As discussed above, when $C$ is invertible, the upper and lower bound on the critical value $\lambda_c$ coincide. We choose the discrete time LTI system with $A = -1.25, C = 1$. The noise $w_t$ and $v_t$ have zero means and variance $R = 2.5$ and $Q = 1$. The 2-description MD code is designed according to [21] such that the central MSE $D_0 \approx 8.33 \times 10^{-6}$ and $D_1 \approx 1.56$. According to the results in Section III, we can get $R_0 \approx 2.5$ and $R_1 \approx 4.06$.

Fig. 4 shows the expected estimation error covariance with different coding schemes. Using MD coding, the asymptote $\lambda_c$ has been pushed from 0.36 to 0.2. The convergence properties of error covariance at high packet loss rate region has been improved dramatically.

Some simulations have also been done in MATLAB by implementing the MD encoder and decoder. We repeated each scenario 2000 times and used the average values as the approximations. In Fig. 4, the simulation results are consistent to the theoretical limits very well. Some of the simulation points are below the lower bound near the critical $\lambda_c$ value because we only run simulation over 2000 time steps and the covariances take longer time to converge.

Fig. 5 shows some additional simulation results. For each certain packet dropping rate, the center of the error bar is the mean value and 95% of the simulation results are inside the error bar. It’s clear that if we use 3-description coding, the critical value $\lambda_c$ will be pushed even further. So the benefits of using MD are clear and the cost we need to pay
is more bpss. When we keep bpss constant, as shown in Fig 6, generally speaking, we will lose some accuracy as long as the number of descriptions increases. Comparing with the previous figure, there are not obvious differences due to the accuracy loss. Of course, this depends on how sensitive the dynamic system and kalman filter are to the accuracy of the sample values.

Fig 7 shows the details about the error covariance when packet dropping rate is relative low, say smaller than 40%, and MD scheme gives much better performance and robustness than single-description scheme. Note, the 2-description MD achieves almost as good performance as sending single description code twice and saves up to 40% bandwidth at the same time.

VI. MD CODING OVER GILBERT-ELLIOT MODEL

So far, we have dealt with the situation when the packet loss due to the channel is according to an Bernoulli loss model. However, as it is well known, another popular model for packet drops in many channels (such as the wireless channel) is one in which the losses occur in bursts. This bursty error behavior can be captured by a discrete-time Markov chain model. The simplest of such models is the famous Gilbert-Elliot channel model. This model considers the channel as existing in two possible states - 'Good' and 'Bad'. In the good state, the packet drop probability is 0 while the bad state corresponds to packets being dropped. The channel transitions between these two states according to a Markov chain with transition probability matrix \( Q \). Clearly, the model can easily be made more complicated by considering more than 2 states with different probabilities of packet drop. However, for reasons of simplicity and without loss of generality, we will consider only the 2-state model.

The analysis of the Markov channel case proceeds along similar lines as outlined above. Suppose the channel can be modeled as a 2-state Markov chain with transition probability matrix \( Q \) given by

\[
Q = \begin{bmatrix} q_{00} & q_{01} \\ q_{10} & q_{11} \end{bmatrix},
\]

where 0 is the good state, 1 is the bad state, and \( q_{ij} \) is the probability from the previous state \( j \) to the next state \( i \). For the case of 2-MD code, we are thus interested in a 4-state Markov chain where the states correspond to both packets lost, only the 1st description packet lost, only the 2nd description packet lost and no packet lost. The transition probability matrix of this chain is given by

\[
\tilde{Q} = \begin{bmatrix} q_0^2 & q_{00}q_{10} & q_{00}q_{11} & q_{01}q_{11} \\ q_{10}q_{00} & q_{10}q_{10} & q_{10}q_{11} & q_{11}^2 \\ q_{01}q_{00} & q_{01}q_{10} & q_{01}q_{11} & q_{11}^2 \\ q_{11}^2 & q_{11}^2 & q_{11}^2 & q_{11}^2 \end{bmatrix}.
\]

Note that the state in which both packets are lost is equivalent to no observation coming through, while all the rest of the states correspond to the system being observed. We need results analogous to the Bernoulli case when packets are being dropped according to a Markov chain. We use the following results proven in [10].

Proposition 6.1: Consider the system

\[
x_{k+1} = Ax_k + w_k,
\]

being observed through \( n \) sensors with the \( i \)-th sensor of the form

\[
y_i^j = C_i^j x_k + v_i^j.
\]

Suppose only one sensor can be active at any time instant and the choice of the sensor is done according to a Markov chain with transition probability matrix \( Q = [q_{ij}] \). Denote the Ricatti update in error covariance when the \( i \)-th sensor is used by \( f_i(.) \) and denote

\[
f_{i}^k (\cdot) = f_i(f_i(\cdots (\cdot))))_{k \text{ times}}
\]

Then the expected error covariance at time step \( k \), denoted by \( E[P_k] \) is bounded as follows.

- Upper bound 1: Denote \( q_i = \max_j q_{ji} \) and \( \pi_i \) is the initial probability of states \( i \). Then an upper bound for \( E[P_k] \) is \( X_k \) where

\[
X_{k+1} = \begin{cases} \sum_i q_i f_i(X_k) & k \geq 1 \\ \sum_i \pi_i f_i(P_0) & k = 0. \end{cases}
\]

Thus a sufficient condition for convergence of the error covariance is that \( X_k \) converges as \( k \) progresses.

- Upper bound 2: Another upper bound for \( E[P_k] \) can be given by \( Z_k \), where

\[
Z_k = \sum_{j=1}^{n} Z_k^j,
\]

and \( Z_k^j \)'s evolve according to the coupled equations

\[
Z_{k+1}^j = \sum_i q_{ji} f_i(Z_k^j).
\]
Lower bound: Denote the probability of being in Markov state $j$ at time step $k$ by $\pi_{j}^{k}$. Then a lower bound for $E[P_{k}]$ is $Y_k$ where

$$Y_k = \theta_{jj}^{k-1}\pi_{j}^{0}P_{0} + \sum_{i=1}^{k} \theta_{jj}^{i-1}(\pi_{j}^{i+1} - \theta_{jj}^{i})f_{j}^{k}(\Sigma),$$

where $\Sigma$ is the covariance matrix of the process noise $u_k$. Note that one such lower bound exists for each $j$. Thus a necessary condition for divergence of the error covariance is that

$$q_{jj}|\lambda_{\text{max}}(A_j)|^2 > 1,$$

where $\lambda_{\text{max}}(A_j)$ is the maximum magnitude among the eigenvalues of the unobservable part of $A$ when $(A, C^j)$ is put in observer canonical form.

We can easily apply these results to our case with the transition probability matrices described above. We consider the same example as in the previous section. When no MD code is applied, the system transitions according to a Markov chain between a state in which the system is observed and one in which it is not. With a 2-MD code, the four states corresponding to the transition probability matrix shown before. We can easily see the improvement in performance by using MD codes. In figure 8 we plot the upper and lower bounds for the error variance as a function of $q_{10}$ for the value $q_{10} = 0.95$. Although only the bounds are plotted, the lowering of the lower bound is indicative of the performance getting better with MD-codes. This fact can be verified by actually simulating the system in the two cases. The results for parameters $q_{11} = 0.05$ and $q_{11} = 0.95$ are shown in figure 9.

![Fig. 8. Upper and lower bounds for Markov chain case](image)

It can be seen from the figures and the expressions given above that while the system diverges at $q_{10} = 0.36$ for no MD code case, for the 2-MD code case, it diverges at $q_{10} = 0.2$. Thus the system stability margin is increased. It can actually be proven in this case (when the observation matrix $C$ is invertible) that the necessary condition for divergence is sufficient as well.

VII. CONCLUSION AND FUTURE WORKS

In this paper, we present a new scheme for the state estimation in NCS to compensate packets dropping: using multiple description source coding to transfer the observer’s outputs. In this scheme, we use $L \geq 2$ descriptions to represent each source sample instead of one description. The accuracy of the output of decoder only depends on how many descriptions has been successfully received in a certain time interval. We consider about two channel models: Bernoulli loss model and Gilbert-Elliott model. In the high rate case, the estimation error covariance converges over a much larger receiving probability area than using traditional single description source coding. Also, the scheme is better than sending measurement $L$ times because it saves considerable bandwidth.

The main purpose of this paper is trying to understand NCS from another angle: at the high bit rate scenario, what can we do to compensate the packet loss? The work in this paper is very helpful to understand the impact of lossy networks and how to counteract it.

There are several issues we can look into in the future. First of all, we need a more complete theory to understand the MD coding for $L \geq 2$ case. Second, the validity of the quantization noise model of MD coding may need to be verified more carefully. Third, since MD coding will greatly increase the computation complexity of the decoder, a more efficient search algorithm for the source coding will be greatly helpful. Last, we hope to get some similar results for the stability of the closed loop NCS.

VIII. ACKNOWLEDGEMENTS

The authors are grateful to M. Effros for exchanging ideas of MD coding. They also want to thank A. Tiwari and D. G. MacMynowski for the discussions and comments.
