Problem set 3 **Out F 31/Oct Due W 12/Nov in class**

1. Call a 0 - 1 matrix "nine-free" if there is no 3×3 submatrix with all entries one. (Rows and columns need not be consecutive.) Let $f(n)$ denote the maximal number of ones in an $n \times n$ nine-free matrix. Find a lower bound for $f(n)$ – i.e., show, for α as large as possible, that there exists a nine-free $n \times n$ matrix A with at least α ones. *Hint:* Use the deletion method, first letting $P(A_{ij} = 1) = p$ and then changing a one to a zero in every 3×3 submatrix with all entries one.

2. (a) Let A be a random $n \times n$ matrix with entries chosen independently and uniformly in $\{0, 1\}$. Find the expectations of the determinant and the permanent of A.

   Note: You are certainly familiar with the first of these concepts, possibly not with the second; they are defined by the formulas

$$\det(A) = \sum_{\sigma \in S_n} \text{sign}(\sigma) \prod_1^n A_{i,\sigma(i)}$$

$$\text{perm}(A) = \sum_{\sigma \in S_n} \prod_1^n A_{i,\sigma(i)}$$

   (b) Let A be a random $n \times n$ matrix with entries chosen independently and uniformly in $\{\pm 1\}$. Find $E((\det(A))^2)$.

3. A *monotone* function $f : \{0, 1\}^n \to \{0, 1\}$ is one with the property that if $f(\ldots, x_{i-1}, 0, x_{i+1}, \ldots) = 1$ then $f(\ldots, x_{i-1}, 1, x_{i+1}, \ldots) = 1$. Here are some examples: the "dictator function" $\text{Dict}_{n,i}(x_1, \ldots, x_n) = x_i$; the AND_n function which is 1 only for $x_1 = \ldots = x_n = 1$; the function MAJ_n for odd n which is 1 if more than half the inputs are 1's; the function $\text{CLIQUE}_{n,k}(x_{1,1}, x_{1,2}, \ldots, x_{n-1,n})$ which is 1 if the graph having an edge for each "1", contains a clique of size k.

   When we design boolean circuits for functions, we use a fixed (and constant-size) basis of gates. For instance the basis $\{\text{AND}_2, \text{NOT}\}$, or even just the basis with the single gate $\{\text{NAND}_2\}$. If we are only interested in computing monotone functions, however, then we can consider using a basis consisting only of monotone gates. This is not necessarily the simplest or most efficient way of constructing a circuit. For instance the simplest way to compute MAJ_n is to use a general (non-monotone) basis to perform arithmetic, and add up the input bits and check whether the sum is $> n/2$. In order to understand the power of nonmonotonicity, even for computing monotone functions, we need to ask how efficiently we can compute functions like MAJ_n using only a monotone basis. That is what we will do in this exercise.

   The basis we consider is simple: it includes only the 3-input gate MAJ_3. Your task is to show something not at all obvious: there are log-depth circuits for MAJ_n consisting solely of MAJ_3 gates.

   Hints:

   (a) There exists a circuit of the following simple form: the MAJ_3 gates form a complete 3-ary tree from the output gate all the way down to input wires at depth $O(\log n)$. Then each of these wires is randomly, independently, hooked up to one of the n inputs. (Note, each input will be used many times.)

   (b) A good approach is to show that for any particular $x = (x_1, \ldots, x_n)$, with very low probability the circuit you constructed at random gives the wrong answer.

   (c) For any particular x, let p_t be the probability that a wire at level t of the circuit carries a value that disagrees with $\text{MAJ}_n(x)$. Show that $p_1 \leq (n-1)/(2n)$ and $p_{t+1} = 3p_t^2 - 2p_t^3$.

4. The following is an example of a heavy-tailed distribution. μ is supported on the nonzero integers,

$$\mu(m) = K/m^4$$

for the appropriate normalizing constant K which is $45/\pi^4$.

The first and second moments of μ are well-defined; if you calculate you'll see $E(X) = 0$, $\mathrm{Var}(X) = 15/\pi^2$.

The purpose of this exercise is to demonstrate that for a heavy-tailed distribution like this, taking the average of a large number of independent samples does *not* create a light-tailed distribution.

Specifically, take n iid rvs $X_1, \ldots, X_n$ with the distribution μ, and set $\overline{X} = (1/n) \sum X_i$. The second-moment inequality tells us:

$$\Pr(|\overline{X}| \geq \lambda \sqrt{\mathrm{Var}(\overline{X})}) \leq \frac{1}{\lambda^2}$$

(Specifically $\Pr(|\overline{X}| \geq r) \leq \frac{15}{\pi^2 n r^2}$.)

Show that there is a polynomial $p(\lambda, n)$ such that

$$\Pr\left(\overline{X} > \lambda \sqrt{\mathrm{Var}(\overline{X})}\right) \geq 1/p(\lambda, n).$$

What does this tell you about the moment generating function of μ?
